Exchange Rate Regime and Wage Determination in Central and Eastern Europe

Abstract

After the eastern enlargement of the European Union due to increasing labor market integration, wage determination and monetary integration in Central and Eastern Europe have become key issues in European economic policy making. Based on the Scandinavian model of wage adjustment by Lindbeck (1979), we intend to analyze the role of exchange rates in the wage determination process of the Central and Eastern European countries to identify which exchange rate strategy contributes to faster wage convergence in Europe. Panel estimations reveal a robust negative relationship between exchange rates and wage growth. This suggests that workers in countries with fixed exchange rates are likely to benefit from higher wage increases.

JEL Code: C23, J30, F31, O52.

Keywords: wage policy, labor markets, exchange rate regime, Central and Eastern Europe.

1. Introduction

Choosing the appropriate exchange rate regime remains an important and controversial economic policy issue for the Central and Eastern European countries (Belke and Kaas 2004, von Hagen and Zhou 2005, Fidrmuc and Korhonen 2006, Schnabl 2008). Although exchange rate stability in CEE has grown since the introduction of the euro different exchange rate strategies persist. While Estonia, Lithuania, Latvia, Bulgaria, Slovenia and the Slovak Republic are pegging their currencies tightly to the euro or have chosen to join the euro area, the Czech Republic, Poland and most recently Hungary allow their exchange rates to be widely determined by market forces. The central bank of Romania manages the exchange rate discretionarily.

At the same time wage determination in Central and Eastern Europe (CEE) has become a key issue in European economic policy making, as large differences in wage levels persist (ECOFIN 2005, European Commission 2007). For instance, labor unions in CEE have tended to claim substantial wage increases to achieve a faster wage convergence to the EU15 (see for instance the Skoda wage bargaining process in the Czech Republic 2007). These claims have been accentuated by the fact that rising production, increasing productivity and labor migration to Western Europe have led to a shortage of (highly-qualified) workers (Goretti 2008). Nonetheless, institutional factors such as the different tax systems, wage rigidities, a low degree of both unionization and collective bargaining have contributed to the persistence of wage gaps (EIRO 2008).

Although both, the choice of exchange rate regime and the wage determination process in Central and Eastern Europe have been subject to extensive academic discussions, until now comparatively few papers have scrutinized the interaction of both, i.e. the role of exchange rates for wage setting in Central and Eastern Europe. According to Mundell's (1961) seminal theory of optimum currency areas, a high degree of wage flexibility is required if exchange rates are irrevocably fixed and heterogeneity within the monetary union remains high. Based on this criterion, Paas et al. (2002), Belke and Kaas (2004), Gruber (2004), Iara and Traistaru (2004) and Babestskii (2007) among others, have analyzed the degree of wage flexibility in CEE.

Belke and Setzer (2003) and Belke et al. (2004) are considering the impact of exchange rate volatility on labor markets in CEE. They argue that exchange rate volatility vis-à-vis the euro significantly contributes to higher unemployment. Schnabl (2008) studies the effect of exchange rate volatility on economic growth in the EMU periphery. He argues that exchange rate stability provides more certainty for the wage bargaining process in small open economies and thereby leads to higher growth and wages.

We will build upon this discussion by examining which exchange rate strategy provides a more favorable framework for the wage setting process in emerging markets leading to faster wage growth in CEE. The investigation will be based on the seminal Lindbeck model of wage convergence during the economic catch-up which will be tested empirically.

2. Theoretical Framework of Exchange Rate Regimes and Wage Determination

The literature dealing with wage determination and exchange rates goes back to the Bretton Woods era. Friedman (1953), Meade (1951) and Mundell (1961) saw exchange rate flexibility as a substitute for wage rigidity in the face of asymmetric shocks. Given flexible exchange rates and rigid wages in small open economies (as they prevail in CEE), a negative (positive) productivity shock is offset by currency depreciation (appreciation). Monetary expansion and depreciation are seen as Keynesian tools to address deflationary shocks and sustain growth and welfare.

In contrast, in the Scandinavian model of wage adjustment (Lindbeck 1979) fixed exchange rates provide a more stable and growth enhancing framework for wage determination in small open economies during the economic catch-up process. In this dynamic extension of the Balassa-Samuelson model (Balassa 1964, Samuelson 1964), fixed exchange rates lead to more certainty in the wage bargaining process as enterprises and trade unions can rely on a more stable macroeconomic environment for the wage bargaining process. The outcome is higher wages than under flexible exchange rate regimes.

In this paper we apply Lindbeck's (1979) approach to CEE. The Scandinavian model which goes back to a group of Norwegian (see Aukrust, Holte and Stoltz 1967) and Swedish

economists (Edgren, Gösta, Faxén and Odhner 1970) and was summarized by Lindbeck (1979)¹ was designed to explain the wage adjustment of the Scandinavian countries in the economic catch-up versus the US. Under the Bretton Woods System of fixed dollar parities, during the 1950s and 60s, Sweden along with Norway and Denmark were among Western Europe’s fastest growing economies. In contrast to the CEE countries today, where different exchange rate strategies coexist, all Scandinavian countries fixed their currencies to the dollar. The Scandinavian model of wage adjustment had the basic idea that nominal wage growth is driven by productivity increases and inflation. Domestic inflation was expressed in terms of world inflation and exchange rate developments.

One basic assumption of the Lindbeck model is that purchasing power parity holds: Given perfect arbitrage, domestic price inflation in the tradable good sector Δp_T^d is assumed to be equal to inflation on world traded good markets (measured in terms of the dominant international money) labeled as Δp_T^w , plus the rate of currency appreciation/ depreciation Δe . Formally,

$$\Delta p_T^d = \Delta p_T^w + \Delta e, \tag{1}$$

While Lindbeck assumed the dollar to be the dominant international money, we assume that the euro is the dominant reference currency for CEE as most international goods and financial flows in CEE are denominated in euros (ECB 2008). The Scandinavian authors in the 1960s did not consider exchange rates to be important policy variables since the Scandinavian exchange rates were tightly fixed to the dollar and exchange rate changes were (close to) zero. They assumed that arbitrage in international traded goods markets ensured that inflation in the domestic traded goods sector converged to inflation in the dollar denominated world traded goods markets as in equation (1).

Lindbeck (1979) further assumed that the wage bargaining process was initiated in the (industrial) tradable goods sector, where labor productivity tends to grow faster than in the non-tradable (service) sector.² As workers are aware of increasing productivity, they bargain fiercely

¹ For an empirical analysis of the Lindbeck model for the Scandinavian countries see Forslund et al. (2006).

² In contrast, Goretti (2008) argues that the wage bargaining process may start in the (non-traded goods) public sector and is transmitted to the other sectors of the economy.

for respective wage increases. Let Δq_T^d be the productivity growth in the tradable sector, reflecting increasing stocks of human and physical capital. The trade unions in the "unsheltered" tradable sector are assumed to orient their wage bargaining on productivity gains plus eventual price increases of tradable goods world market prices Δp_T^d . Therefore, the average rate of the nominal wage increases in the tradable sector Δw_T^d is characterized by:

$$\Delta w_T^d = \Delta p_T^d + \Delta q_T^d. \quad (2)$$

According to Lindbeck in small open economies (such as in CEE) the wage bargaining process can be regarded as being constrained by fixed exchange rates. If trade unions bargain for nominal wage increases beyond equation (2), manufacturing goods become uncompetitive in world markets with a fall in employment.³ While wage increases beyond equation (2) may be possible in the short-run, in the long-run trade unions would return to equation (2) to avoid rising structural unemployment. Thus, equation (2) defines the natural (long-run) rate of nominal wage increases in a small open economy. As long as inflation in world prices p_T^w remains low and fairly predictable, workers are content to bargain for the concurrent trends in domestic productivity growth and world inflation.

As in the Balassa-Samuelson framework, Lindbeck (1979) assumed that labor "solidarity" and labor mobility between the manufacturing sector and the non-tradable sectors transmit the manufacturing wage increases to wage increases in the service sector w_{NT}^d :

$$\Delta w_T^d = \Delta w_{NT}^d = \Delta w^d, \quad (3)$$

where Δw^d denotes the wage growth in the whole economy. As the non-tradable sectors were widely shielded from world markets, prices in these sectors were assumed not to be driven by international competition but would be based on domestic labor costs. Thus, the price increases in

³ It is argued for instance, that recently the real wage increases in the Baltics and Hungary have gone beyond productivity increases.

the non-tradable sector Δp_{NT}^d are a function of wage increases Δw_{NT}^d subtracting the productivity gains in the non-traded goods sector Δq_{NT}^d , where productivity increases in the non-tradable (service) sector were assumed to be smaller than in the traded goods sector:

$$\Delta p_{NT}^d = \Delta w_{NT}^d - \Delta q_{NT}^d, \text{ with } \Delta q_{NT}^d < \Delta q_T^d. \quad (4)$$

The equations (1), (2), (3) and (4) yield equation (5) which shows the impact of world market prices, exchange rate changes and relative sectoral productivity gains on prices of non-traded goods:

$$\Delta p_{NT}^d = \Delta p_T^W + \Delta e + \Delta q_T^d - \Delta q_{NT}^d. \quad (5)$$

In the Scandinavian model, the wage bargaining and price adjustment processes in the traded and non-traded goods sectors affect general inflation Δp^d , which is defined as a composite of traded goods inflation and non-traded goods inflation given the respective weights α and $(1 - \alpha)$ in the consumer basket:

$$\Delta p^d = \alpha \Delta p_T^d + (1 - \alpha) \Delta p_{NT}^d. \quad (6)$$

Inserting equations (1), (5) and (6) yield equation (7) which can be interpreted as an overall measure for supply-driven inflation in a small open economy in the economic catch-up process:

$$\Delta p^d = (\Delta p_T^W + \Delta e) + (1 - \alpha)(\Delta q_T^d - \Delta q_{NT}^d). \quad (7)$$

In equation (7) the term $(\Delta p_T^W + \Delta e)$ is equivalent to imported inflation. If world market prices in the traded goods sector rise (fall) and/or if the exchange rate depreciates (appreciates), this would fuel domestic inflation (deflation). The term $(1 - \alpha)(\Delta q_T^d - \Delta q_{NT}^d)$ captures the structural component of inflation, which is in line with the Balassa-Samuelson effect of supply driven

inflation (Balassa 1964 and Samuelson 1964).⁴ Relative productivity gains in the tradable goods sector ($\Delta q_T^d - \Delta q_{NT}^d > 0$) are translated via the wage bargaining process into higher inflation. The greater the weight of the non-tradable goods sector in the economy ($1 - \alpha$), or the larger the difference between productivity growth of the tradable and the non-tradable goods sector, the larger the impact on domestic inflation.

3. Wage Adjustment in Labor Markets under Alternative Exchange Rate Regimes

Whereas the Lindbeck model was originally constructed for the Scandinavian countries which pegged their currencies to the dollar, today the CEE countries can choose their exchange rate strategies (see Table 1): The Baltics have chosen a hard peg to the euro within the Exchange Rate Mechanism 2 and aim to adopt the euro as a legal tender as soon as possible. In contrast, the monetary authorities of Czech Republic, Hungary and Poland have implemented an inflation targeting frameworks and let their exchange rates float (more or less) freely. They have continued to postpone the euro adoption targets.

Figure 1 shows the de facto quarterly exchange rate changes of the CEE countries currencies against the euro (before 1999 the DM). There are two clusters. The first group of countries, namely Czech Republic, Slovak Republic, Hungary and Poland allowed their exchange rate to float to a high degree, while the second group, the Baltic countries and Slovenia, exhibit low exchange rate volatility against the euro. The Estonian currency board is pegging the kroon tightly to the euro (or DM) in the whole observation period. Lithuania and Latvia pegged their currencies to the dollar and a currency basket before pegging them to the euro. With the introduction of the euro in January 2009, Slovakia will shift from widely flexibly to a “tightly fixed” exchange rate. Choosing alternative exchange rate strategies will have different implications for the wage setting process in the economic catch-up. Following De Grauwe and Schnabl (2005), we show that the industrial catch-up of emerging markets under alternative exchange rate strategies leads to two alternative outcomes depending on the monetary framework: First, if exchange rates are pegged, the relative productivity gains drive up prices as in the seminal Balassa-Samuelson model.

⁴ Schnabl (2008) discusses the possible shortcomings of the Balassa-Samuelson approach.

Table 1: Exchange rate strategies in CEE in 2008

Country	Current exchange rate system	Euro adoption
CZ	Free floating with inflation target since 1997, from 1995 till 1997 managed float	The preliminary target date (1 January 2010) was withdrawn by the government on 25 October 2006. No new date has been officially set for the time being.
EE	Currency board with a hard peg to the euro within the ERM II (since June 2004)	EE targets euro area membership as soon as possible (2011 being the earliest possible envisaged date according to current inflation forecasts).
HU	Free floating since March 2008, before managed floats, with inflation target since 2002	The Convergence Programme of 1 December 2006 aims at meeting the Maastricht criteria in 2009. A new target date for the adoption of the euro has not been specified.
LT	Currency board with a hard peg to the euro within the ERM II (since June 2004), before hard dollar peg	The specific target date has not been set. According to the government, LT will aim to join the euro area as soon as possible and the more favourable period to join starts from 2010.
LV	Currency board with a hard peg to the euro within the ERM II (since May 2005), before currency basket	The specific target date has not been set.
PL	Free floating with inflation target since 2000, from 1995 till 2000 managed float	The specific target date has not been set.
SK	ERM II membership (exchange rate with 15 percent fluctuation band) since November 2005, before managed floats	January 2009
SI	EMU membership since January 2007, before ERM II membership (exchange rate with 15 percent fluctuation band) since June 2004	January 2007

Figure 1: Exchange rate changes, quarter-over-quarter

Source: IMF, 2008.

Second, if exchange rates are freely floating and the central banks follow an inflation target, relative productivity gains are accompanied by nominal appreciation. Even if both monetary frameworks can be seen as equal policy choices to engineer the real appreciation which is the natural outcome of industrial catch-up, exchange rate volatility and sustained nominal appreciation may increase uncertainty in labor markets.

Based on the Scandinavian model we derive the implication for the wage determination process in emerging markets under alternative exchange rate regimes. From equation (2), (3) and (4) we define the overall wage growth as the sum of overall productivity growth and inflation:

$$\Delta w^d = \Delta p^d + \Delta q^d, \quad (8)$$

where Δq^d denotes the overall general domestic productivity growth, which is a composite of traded goods and non-traded goods productivity growth given the respective weights ρ and $(1 - \rho)$:

$$\Delta q^d = \rho \Delta q_T^d + (1 - \rho) \Delta q_{NT}^d. \quad (9)$$

Inserting equations (7) and (9) in (8) yields equation (10), which can be interpreted as a measure for the overall long-run supply driven nominal wage growth in CEE:

$$\Delta w^d = \tau(\Delta q_T^d - \Delta q_{NT}^d) + (\Delta p_T^w + \Delta e), \quad (10)$$

where $\tau = (\rho - \alpha + 1)$ is a positive constant term. According to equation (10) nominal wage growth is driven by productivity gains of the tradable goods sector relative to the non-tradable goods sector as well as by imported inflation in the traded goods sector and exchange rate changes $\Delta p_T^w + \Delta e$.

The wage setting process can occur within two institutional environments. In countries pegging their exchange rates tightly to the euro, for instance Lithuania, Latvia or Estonia, the term Δe is equal (or close) to zero. This reduces the uncertainty for the wage bargaining process, because trade unions and enterprises have solely to predict future productivity gains and traded goods inflation. In addition, in the Lindbeck model it is assumed that the biddings of trade unions for higher wages are constrained by the fixed exchange rate. Trade unions reap the full benefits of productivity gains and equilibrate the international competitiveness between CEE and the euro area. But, trade unions would not want to ask for wage increases above domestic productivity

gains as this would erode the enterprises' international competitiveness. If they would bid for wage increases above this level, profits of enterprises would shrink and entrepreneurs would be less willing to increase wages in the next bargaining period.

In countries with freely floating exchange rates such as Poland or the Czech Republic an additional factor of uncertainty is introduced into the wage bargaining process as exchange rate volatility is high. To project future profits the enterprises in CEE have to know how the future exchange rate will be. If the exchange rate is regarded as an asset price which follows a random walk, there is uncertainty because the exchange rate may appreciate or depreciate. If – due to the Balassa-Samuelson effect – firms expect an appreciation of the domestic currency, they are reluctant to commit to wage increases as export revenues may decline. Therefore, we follow McKinnon and Schnabl (2006) and include a risk premium ψ in equation (10), which captures discounts on wages originating in uncertainty arising from exchange rate fluctuations. The risk premium is assumed to be negative as (parts of) the costs of this uncertainty are passed through to workers. This implies:

$$\Delta w^d = \tau(\Delta q_T^d - \Delta q_{NT}^d) + (\Delta p_T^W + \Delta e) + \psi \quad (11)$$

While in countries with an exchange rate peg ψ and Δe are assumed to be (close to) zero, the exchange rate uncertainty in countries with flexible exchange rate regimes implies a negative risk premium on wages ($\psi < 0$).

4 Estimation Framework

We investigate whether equation (11) holds for the CEE countries from an inter-temporal and cross-section perspective. We include eight CEE countries in our panel, which entered the European Union in May 2004, namely Czech Republic (CZ), Estonia (EE), Hungary (HU), Lithuania (LT), Latvia (LV), Poland (PL), Slovak Republic (SK), and Slovenia (SI). Bulgaria and Romania, which joined the European Union in January 2007, are omitted due to missing (wage) data.

4.1 Data

Our sample starts in the first quarter of 1996 and ends with the second quarter of 2007. Before 1996 data on the former transition economies is very fragmented. We use quarterly data, which is the smallest available frequency for all considered time series.⁵ Nominal gross wages are from national statistics. Exchange rates (quarterly averages), inflation and productivity are drawn from Eurostat and IMF International Financial Statistics. Euro area tradable goods prices p_T^W are proxied by German export prices as export prices for the euro area are not available, and Germany is the largest country in the euro area.⁶ As a proxy for productivity we use nominal GDP per capita, because industrial and service sector production per employee are not available for the whole time period for every country at quarterly frequencies. As alternative productivity measure we use the ratio of consumer (CPI) to producer prices (PPI) analogous to De Grauwe and Schnabl (2005). Following Balassa (1964) and Samuelson (1964), this measure regards relative price increases of non-traded goods versus traded goods as a proxy for relative productivity gains.

The quarterly averages of exchange rates are in price notation, which implies that a negative exchange rate change indicates an appreciation of the national currency against the euro. As proxies for the risk premium arising from exchange rate volatility we use the absolute and squared values of exchange rate returns. In addition, we consider intra-quarter realized volatilities, standard deviations of daily exchange rate changes and the z-score as proposed by Ghosh, Gulde and Wolf (2003). With the exception of the volatility measures all time series are year-over-year quarterly growth rates.

4.2. Descriptive Statistics

Equation (11) implies that controlling for exchange rate changes, world traded goods inflation and relative productivity changes, countries with fixed exchange rates have a higher real wage

⁵ To adjust data seasonally, we calculate year-over-year growth rates instead of quarter-over-quarter growth rates.

⁶ As alternative inflation measures, the harmonized consumer price index as well as the producer price index of the euro area (EU-12) have been used. Both proxies lead to similar results which are available upon request.

growth. Note that domestic traded goods inflation has been substituted by euro area traded goods inflation and exchange rate changes. Therefore, the descriptive statistics focus on real wage growth. In contrast to the regressions in section 4.3., the descriptive statistics do not control for other determinants of real wages as in our Balassa-Samuelson specification. Given this caveat countries with hard pegs (to the euro) (i.e. LT, LV, EE) are expected in line with the Balassa-Samuelson model to exhibit higher inflation than countries with flexible exchange rates (PL, CZ, HU, SK), and higher real wages.

Figure 2 displays the real wage growth of the CEE countries since 1996. We observe that real wage growth tends to be higher in the Baltics than in countries with flexible exchange rates. Comparing the two corner solutions, Poland (free float) and Estonia (hard peg), real wage growth in Estonia has been significantly higher than in Poland.

Table 2 displays the descriptive statistics of real wage growth in the individual countries. In general, they support the conclusions drawn from the Lindbeck model. The mean and median of real wage growth in countries with fixed exchange rates are higher than wage growth in countries with free floats; e.g. Latvia has a real wage growth of 4.4 percent per year on average, while the real wage growth of Poland is on average 2.3 percent. Estonia has with an average real wage growth of 6.3 percent the greatest wage growth, while the Slovak Republic with a real wage growth of 2.1 percent has the smallest.

A t-test (t_1) which analyzes whether the individual means differ from the group mean, indicates that all means are different from the pooled mean. The average real wage growth of countries with a fixed exchange rate peg is significantly higher wage growth than the group mean, while in countries with flexible exchange rates – with the exception of Czech Republic – the average wage growth is below the pooled wage growth of 3.8 percent.⁷ The F-test provides information with respect to equality of all means. The null hypothesis of equal means is rejected for all countries which implies that the average real wage growth differs between all new member states.

⁷ An alternative t-test (t_2) shows that the individual means are significantly different from zero.

Figure 2: Real wage growth, year-over-year

Source: National statistics, 2008 (drawn from Reuters Econwin).

The Fisher-ADF panel unit root test (Choi 2001, Madalla and Wu (1999)) is based on individual p-values for the unit root hypothesis which are combined in a second step to obtain an overall p-value. It does not find evidence for unit roots in the investigated panel. Henceforth, neither panel cointegration nor spurious regressions are a matter of concern. Motivated by these findings, we examine if there is a positive systematic relationship between exchange rate stability and wage growth in CEE.

Table 2: Descriptive statistics, real wage growth (y-o-y, quarterly data)

Country	Mean	Median	Max.	Min.	Std. dev.	Obs.	t ₁	t ₂
CZ	0.040	0.038	0.080	-0.004	0.019	44	12.243 (0.000)	5.430 (0.000)
EE	0.063	0.066	0.118	-0.015	0.026	44	15.317 (0.000)	10.203 (0.000)

SI	0.034	0.037	0.087	-0.0085	0.018	44	-3.548 (0.001)	-9.343 (0.000)
All	0.038	0.031	0.184	-0.185	0.043	352		
<i>F</i>	63.971	(0.000)						

Notes: t₂ is the t-statistic for the hypothesis that the mean is zero. t₁ is the t-statistic for the null hypothesis that the individual mean does not significantly differ from the overall group mean. *F* is an F-statistic for the hypothesis that all means are equal. P-values are reported in parentheses.

4.3. Estimation framework

We estimate the Lindbeck model as in equation (11) for a CEE cross-country panel to identify the impact of exchange rate volatility on nominal wage growth. To specify the model properties we test for random effects against fixed effects.

The Hausman-test gives a chi-squared distributed statistic of 2.184, and a p-value of 0.702 in favor of a random effects specification.

Based on equation (11) we estimate the following model:

$$\Delta w_{it} = \bar{\mu} + \beta \Delta q_{it}^{diff} + \lambda \Delta p_t^W + \gamma \Delta e_{it} + \phi \psi_{it} + u_{it} \quad \text{with } u_{it} = \mu_i + v_{it}, \quad (12)$$

where Δq_{it}^{diff} is the productivity differential, $i=1, \dots, 8$ denotes the cross-section and $t=1996Q1, \dots, 2007Q2$ the time dimension. The term $\bar{\mu}$ denotes the overall constant, while μ_i denotes the country-specific deviations from $\bar{\mu}$. The random effects specification assumes that the country-specific effects are realizations of independent random variables with mean zero and finite variance. Most importantly, the random effect specification assumes that the individual country specific effect is uncorrelated with the idiosyncratic residual v_{it} . The estimation of the covariance matrix for the composite error uses the quadratic unbiased estimators from Swamy-Arora. The parameters are estimated with generalized panel least squares and we use White period standard errors (White 1980, Arellano 1987) to cope with possible cross-sectional heteroscedasticity and serial correlation.

4.4. Results

The estimation results are reported in Table 3 for the baseline regressions, where equation (12) is estimated with GDP per capita growth as productivity measure, German export price inflation as proxy for international traded goods prices, exchange rate changes in price notation and the different volatility measures described in the data section.

In the baseline regression (Table 3, column 1) with squared exchange rate changes as volatility measure all estimated parameters have the expected sign. The productivity measure and the exchange rate term are significant at the common levels. In the lower part of the table the individual country effects μ_i are displayed. To derive individual constant terms the country-specific terms have to be added to the overall constant term. The country specific constant terms are in comparison to a fixed effect model not deterministic, but random. This allows capturing country-specific effects in our heterogeneous panel. However, due to its random character, the different random effects can not be compared with each other.

All signs of the estimates are congruent with the Lindbeck model. Increasing productivity (positive β term) is linked to increasing wages at the common significance levels. Changes in German export prices (as proxy for euro area traded goods inflation) (λ term) have no significant impact on nominal wage growth.⁸ The γ coefficient, which captures the impact of exchange rate changes on wages, has the expected positive sign at the 1 % significance level.

If home currency is appreciating (depreciating) against the euro ($e < 0$ ($e > 0$)) nominal wages decline (increase). This implies that the exchange rate regime has a significant impact on wage determination in the eight analyzed CEE countries.

Among productivity growth, euro area tradable goods inflation and exchange rate changes, exchange rate changes have the highest impact on nominal wage growth as indicated by the largest coefficient. A ten percent exchange rate appreciation (depreciation) is linked to roughly five percentage points lower (higher) wage growth.

Table 3 reports our baseline regression with different volatility measures to check the sensitivity of our results. Alternatively to squared returns, we consider absolute exchange rate changes (modulus) as well as a realized volatility measure that is based on daily intra-quarter information (for the compilation see Andersen et al. 2003). Realized volatility aggregates information from higher frequencies to obtain more accurate estimates of unobserved intra-period volatility. Another volatility measure is the standard deviation of daily exchange rate changes. The z-score (the root of the squared mean of exchange rate changes and its variances) as proposed by Ghosh, Gulde and Wolf (2003), links exchange rate changes and its standard deviation.

Estimating equation (13) with different volatility measures does not change our main conclusion. All parameters originating in the Lindbeck model remain widely unchanged. Productivity growth increases nominal wage growth, while tradable goods inflation in the euro area has no significant impact on wages. Currency appreciation (depreciation) against the euro lowers (increases) nominal wage growth. The size of the coefficients β , λ and γ remains widely the same.

⁸ In a shorter sample which starts in 1999 the λ -terms turns positive and significant.

Table 3: Panel estimation results, baseline regressions

	Squared returns	Absolute returns	Realized volatility	Std. dev.	Z-score

The results for different measures of exchange rate volatility differ within the regressions. Absolute returns, realized volatility, and the z-score proxies for uncertainty have the expected negative sign but only the absolute returns are statistically significant at the common levels. In contrast, the ϕ coefficient is positive for the standard deviation but remains insignificant.

The estimated country-specific μ_i coefficients show (for all regressions) that with the exception of Hungary and Lithuania, countries pegging their exchange rate to the euro have a higher country-specific constant term. All in all, the evidence for a significant effect of the exchange rate regime on wages is strong as all exchange rate terms and four out of five of the risk premium-terms have the expected sign mostly at significant levels.

4.4. Robustness Checks

We have performed a set of robustness checks. First, we estimated our baseline regressions with an alternative productivity measure. Relative changes of consumer versus producer prices were used as a proxy for relative productivity changes. The estimated results are reported in Table 4.

As in the baseline regression from the previous section, higher productivity growth is linked to higher wage growth. Euro area tradable goods inflation has, in contrast to the previous estimation, a positive and significant influence on wage growth. A currency appreciation lowers wage growth (positive γ coefficient). The impact of exchange rate changes on wages is however smaller than in the baseline regressions. A currency appreciation (depreciation) of around ten percent is transmitted via the wage bargaining process into three percent lower (higher) wages. The results are very robust throughout the set of different volatility measures. Euro area tradable goods inflation has the highest impact on nominal wages followed by productivity growth and exchange rate changes.

The ϕ -coefficient isolates the discount on wages due to uncertainty originating in exchange rate volatility. Exchange rate volatility has a significant negative impact on nominal wages when using the squared and absolute exchange rate returns as proxies for exchange rate volatility. Realized volatility, standard deviations as well as the z-score enter the equation insignificantly. To this end, the evidence for lower wages due to exchange rate volatility is mixed. For all regressions country-specific effects are similar to those in the baseline regression. But for Slovenia the country-specific effect turns negative, indicating a smaller constant term than average.

The estimates can be subject to endogeneity bias, in particular with respect to the productivity measures. Higher productivity may drive up wages, but higher wages could also influence productivity. To address this possible endogeneity bias, we implement an instrumental variable estimator (IV). We use a two-stage least squares estimator with White period standard errors

(White 1980). Up to four lags of the endogenous variable as well as of the exogenous variables are used as instruments. The results are shown in Table 5.

The Lindbeck model is widely confirmed for CEE countries and the evidence for a negative impact of exchange rate uncertainty on wage growth is strong. Productivity growth increases wage growth (for the specifications with realized volatility, standard deviation and z-score at highly significant levels). Euro area tradable goods inflation has no significant influence on wages. Exchange rate changes contribute to lower wage growth in times of appreciation. A ten percent appreciation (depreciation) is associated with about five percent lower (higher) wages. Exchange rate volatility has a clearly negative impact on wages for most proxies (ϕ -term). When using squared returns, absolute exchange rate returns or the z-score as proxies the coefficients are negative and highly significant. Otherwise the impact is insignificant. As in the previous regressions, the country specific constant terms remain stable.

All in all we can summarize that there is a high and significant negative relationship between exchange rates and nominal wage growth. The wage bargaining process seems to be strongly influenced under flexible exchange rates. Trade unions and enterprises are forced to predict exchange rate changes next to productivity growth which inputs further uncertainty in the wage determination process. This may result in bargaining for smaller wage increases due to possible losses in competitiveness. The impact of exchange rate volatility on wage growth remains mixed.

In some specifications exchange rate uncertainty is linked with decreasing wages, but in some specifications this effect turns out to be insignificant. Nonetheless, based on the Lindbeck framework our results provide us evidence that the exchange rate regime significantly influences the wage determination process in CEE.

5. Implications for the Wage and Exchange Rate Policies

We analyzed the role of the exchange rate on the wage determination process in CEE. Up to now exchange rate strategies differ across CEE, and there is a controversial discussion about the appropriate exchange rate system during the run-up to the EMU.

The objectives of full employment, fair working conditions, productivity, employment and cohesion are at the centre of EU economic policy. In this context wage policy in CEE is an important issue for European economic policy making due to an increasing degree of labor market integration in the enlarged European Union.

We derived from the Scandinavian model of wage determination that in emerging markets such as in CEE, trade unions could reap a higher benefit in the form of higher nominal and real wage growth in countries with a fixed exchange rate than in countries with flexible exchange rates. Therefore, it is claimed that fixed exchange rates provide a more stable and welfare enhancing framework during the economic catch-up process.

The results from our empirical estimation lead us to the conclusion that flexible exchange rates affect nominal wage growth negatively. As nominal exchange rates appreciate, nominal wages increases are smaller. In addition, there is some evidence that higher exchange rate uncertainty will lead to a discount on nominal and real wage increases, as uncertainty for the wage bargaining process increases. In contrast, pegging the exchange rate tightly to the euro implied that nominal and real wage increases tend to be higher.

The economic policy conclusion is that the Central and Eastern European economies should adopt a fixed exchange rate regime during the economic catch-up process. The finding is in line with Schnabl (2008) who finds higher growth in countries at the EMU periphery with fixed exchange rate regimes. From this perspective, the benefits of higher growth and welfare in countries with fixed exchange rate regimes can be distributed via higher wages granted to the household sector via the wage bargaining process.
